ABSTRACT

In the present paper, two sea slug species, *Biuve fulvipunctata* (Baba, 1938) (Gastropoda Cephalaspidea) and *Taringa tritorquis* Ortea, Perez & Llera, 1982 (Gastropoda Nudibranchia), are reported for the second time in the Ionian coasts of Sicily (Italy). *Biuve fulvipunctata* is an Indo-West Pacific cephalspidean, previously reported for Italian territorial waters only in Faro Lake (Messina, Sicily). *Taringa tritorquis* is a species originally described for Canary Islands and hitherto found in Sicily and probably in Madeira. Both species are easily identifiable for their characteristic external morphology. Indeed, *B. fulvipunctata* shows a W-shaped pattern of white pigment on the head, while *T. tritorquis* presents rhinophore and gill sheaths with spiculous tubercles crown-shaped and an orange-yellowish body coloring. Since *B. fulvipunctata* has been previously reported in Faro Lake, probably, the specimen reported in this note could have been taken in veliger stage through the Strait of Messina currents. Otherwise, the veliger has been carried attached to the keel of boats. Instead, it is still unclear if *T. tritorquis* could be a native or non-indigenous species of the Mediterranean Sea. Indeed, due to its small size and its sciaphilous behavior, it might be a rare species, overlooked until now.

KEY WORDS Aglajidae; *Biuve fulvipunctata*; Discodorididae; Ionian Sea; Sicily; *Taringa tritorquis*.

INTRODUCTION

Recently, two new sea slugs have been found along the central-eastern coast of Sicily. One of them, *Biuve fulvipunctata* (Baba, 1938) is an Indo-West Pacific cephalaspidean of the family Aglajidae Pilsbry, 1895 (1847) (Malaquias et al., 2016; Kousteni et al., 2019), while the other, *Taringa tritorquis* Ortea, Perez et Llera, 1982 is a rare nudibranch of the family Discodorididae Bergh, 1891.

Biuve fulvipunctata was reported for the first time in the Mediterranean Sea as *Chelidonura mediterranea* Swennen, 1961 in 1959, in Antalaya bay (Turkey) (Swennen, 1961). Then, *C. mediterranea* was considered as a junior synonym of *C. fulvipunctata* (Gosliner, 1980; Malaquias et al., 2016). Today, *C. fulvipunctata* has been attributed to the genus *Biuve* Zamora-Silva et Malaquias, 2017 (see Zamora-Silva et al., 2018). In this taxon the external colouring is very variable, with a range from blue with orange/yellow spots and few white patches to

light/dark brown with small white dots. Nevertheless, this species always shows a distinctive W-shaped pattern of white pigment on the head (Zenetos et al., 2004; Kousteni et al., 2019). After the first report in 1959, this species had spread in great part of the Mediterranean Sea, reaching these following localities: Israel in 1986 (Mienis & Gat, 1987), Maltese islands in 1993 (Perrone & Sammut, 1997; Sammut & Perrone, 1998), Cyprus in 2003, 2006 (Tsiakkios & Zenetos, 2011), and 2015 (Malaquias et al., 2016), France in 2014 (Horst, 2015), Balearic islands (Spain) in 2015 (Karachle et al., 2016), Sicily (Italy) in 2015 (Malaquias et al., 2016) and Croatia in 2018 (Kousteni et al., 2019). Moreover, since this species has been found in the Red Sea only twice (Galil et al., 2016), Malaquias et al. (2016) hypothesized that *B. fulvipunctata* entered the Red Sea through the Mediterranean Sea. After that, Galil et al. (2016) have questioned the veracity of this hypothesis. However, to date, the dispersal path of this species is still unknown.

Taringa tritorquis was described by Ortea et al. (1982) based on the finding of three specimens at a depth of 3 m in Lanzarote (Canary Islands). In the original description, it was highlighted a difference in the coloring of specimens with different sizes: individuals of 6 mm have a red-violet body, darker in the middle part and pinker towards the edges of the mantle, while the smaller specimens,

of 4-5 mm, are pinkish-yellow with a darker visceral zone. In all specimens on the notum, there are numerous dark maroon spots with an irregular distribution. Moreover, the notum presents spaced tubercles which have the same shape and color on all the back. The gill is formed by six uni-bipinnate white leaves with red spots. The leaves have a wide triangular rachis and the edge of the rhinophore and gill sheaths have white, spiculous tubercles crown-shaped. Rhinophore sheaths have 6-8 tubercles of this type, while gill sheath has 10 ones. Rhinophores are yellowish-white, with whitish lamellae and some dark spots. Finally, rhinophores have a heart-shaped section, with an anterior groove. Therefore, according to Ortea et al. (1982), this species differs for its distinct external morphology, due to the presence of characteristic tubercles in the rhinophore and the gill sheaths and for the coloring. The first report of *T. tritorquis* in the Mediterranean Sea was based on the finding of two specimens in a station called Santa Maria La Scala, located along the Ionian coast of Sicily (Lombardo & Marletta in Gerovasileiou et al., 2020).

The aim of this paper is to report the second record of *B. fulvipunctata* for the Ionian coasts of Sicily and the second record of *T. tritorquis* for the whole Mediterranean basin. Additional data on these two species are provided.

MATERIAL AND METHODS

The *B. fulvipunctata* specimen was found in a station called Santa Tecla (37.639923 N, 15.184157 E) in the municipality of Acireale, while the *T. tritorquis* specimen was observed in a station called Ognina (37°31'51.7152" N, 15°7'10.5672" E), in the municipality of Catania. Both sites are located along the central-eastern coast of Sicily (Italy). Santa Tecla is a fishing town, which hosts a small touristic port. In particular, the specimen was found in an area near the harbour. Instead, Ognina is a strongly anthropized site, because of the coastal overexploitation, due to the presence of a harbour and a large number of apartment buildings. Geologically, the whole sector is characterized by subvolcanic rocks: columnar basalts and effusive submarine products forming fields of pillow lavas

(Sciuto et al., 2017). Both specimens were identified in vivo and photographed by an Olympus TG-4 Underwater Camera during two different scuba dives conducted by the authors.

RESULTS

On 27th July 2019, a specimen of *B. fulvipunctata* (Figs. 1, 2) was found at a depth of 4.4 m on a thallus of *Padina pavonica* (Linnaeus) Thivy. The specimen was 1.5 cm long and it had a dark blue body colouring with yellowish-orange spots scattered on the surface. On the anterior part of the cephalic shield, it presented a large white W-shaped sign with a yellow edging, which is a diagnostic feature of this species (Swennen, 1961; Malaquias et al., 2016; Kousteni et al., 2019). On the cephalic

shield there was also a white stripe, formed by numerous white dots, in an anterior-posterior direction. The posterior apex of the cephalic shield showed a lot of such points, appearing completely white. Moreover, these white dots were present also along the upper flank of parapods and formed two small transverse stripes on the surface of the visceral hump. The edges of parapods and the posterior limit of the visceral hump presented a row of greater conspicuous white dots. Instead, the *T. tritorquis* specimen (Figs. 3–6) was found on 29th February 2020 at a depth of 6.9 m, under a stone covered by sponges. The specimen was about 8 mm long and had an orange-yellowish body, with the middle part of the notum darker than the marginal parts. On the notum there were orange-brownish patches irregularly distributed mostly in the middle part and dots of the same coloring distributed on all the surface. Both gill and rhinophores were white with maroon spots. Rhinophores had a heart-shaped section. The edge of notum presented bright white dots. The edge of rhinophore and gill sheaths had white spiculous tubercles with a crown shaped. On the notum, there were slight white lines resembling scars, most of which transversely arranged. Therefore, this specimen perfectly corresponds to the first specimen found in Santa Maria La Scala and depicted by Lombardo & Marletta (Gerovasileiou et al., 2020: Fig. 1A). The only difference between these individuals is that the specimen of Santa Maria La Scala presented the slight white lines resembling scars arranged longitudinally.

DISCUSSION

This short note reports the second record of *B. fulvipunctata* in Sicily, after that of Faro Lake (Messina) (Malaquias et al., 2016) and the second record of *T. tritorquis* in the Mediterranean Sea. A case similar to that of *B. fulvipunctata* occurred for another species, *Godiva quadricolor* (Barnard, 1927), a nudibranch of the family Facelinidae Bergh, 1889. In fact, this latter species was found in Faro Lake with stable populations (Furfaro et al., 2018) and then was seen in 2018 in Santa Maria La Scala (Lombardo & Marletta, 2019), a station located near Santa Tecla. Even for *B. fulvipunctata*, many adults' specimens were observed in Faro Lake with established populations (Malaquias et al.,

2016). Therefore, as hypothesized by Lombardo and Marletta (2019) for *G. quadricolor*, the *B. fulvipunctata* specimen could have been carried in veliger stage through the Strait of Messina currents. Another hypothesis could be that the veliger of this species has travelled attached to the keel of some boats and has been brought directly in Santa Tecla.

Instead, the actual distribution of *T. tritorquis* includes Canary Islands, Sicily and probably Madeira (Lombardo & Marletta in Gerovasileiou et al., 2020). Since in Sicily three specimens have been observed throughout three years (from 2018 to 2020), it could be hypothesized that *T. tritorquis* has settled in this area. However, since this species was documented only twice in the Mediterranean Sea (Lombardo & Marletta in Gerovasileiou et al., 2020; present work), there are not enough data to define if *T. tritorquis* is a native or non-indigenous species. Indeed, because of its small size and cryptic behavior, this species is not easy to detect and probably is rare and has been overlooked until now.

Overall, through the present data and the previous observations (Ortea et al., 1982; Lombardo & Marletta in Gerovasileiou et al., 2020), it was checked that *T. tritorquis* is a sciaphilous species that lives in shallow waters (within 10 m), among algae or under the stones probably feeding on sponges, as other species of the genus *Taringa* (Perone, 1985).
